# *% detected as AI

AI detection includes the possibility of false positives. Although some text in this submission is likely AI generated, scores below the 20% threshold are not surfaced because they have a higher likelihood of false positives.

**Caution: Review required.**

It is essential to understand the limitations of AI detection before making decisions about a student's work. We encourage you to learn more about Turnitin's AI detection capabilities before using the tool.

**Disclaimer**
Our AI writing assessment is designed to help educators identify text that might be prepared by a generative AI tool. Our AI writing assessment may not always be accurate (i.e., our AI models may produce either false positive results or false negative results), so it should not be used as the sole basis for adverse actions against a student. It takes further scrutiny and human judgment in conjunction with an organization's application of its specific academic policies to determine whether any academic misconduct has occurred.

## Frequently Asked Questions

**How should I interpret Turnitin's AI writing percentage and false positives?**
The percentage shown in the AI writing report is the amount of qualifying text within the submission that Turnitin's AI writing detection model determines was either likely AI-generated text from a large-language model or likely AI-generated text that was likely revised using an AI paraphrase tool or word spinner.

False positives (incorrectly flagging human-written text as AI-generated) are a possibility in AI models.

AI detection scores under 20%, which we do not surface in new reports, have a higher likelihood of false positives. To reduce the likelihood of misinterpretation, no score or highlights are attributed and are indicated with an asterisk in the report (*%).

The AI writing percentage should not be the sole basis to determine whether misconduct has occurred. The reviewer/instructor should use the percentage as a means to start a formative conversation with their student and/or use it to examine the submitted assignment in accordance with their school's policies.

**What does 'qualifying text' mean?**
Our model only processes qualifying text in the form of long-form writing. Long-form writing means individual sentences contained in paragraphs that make up a longer piece of written work, such as an essay, a dissertation, or an article, etc. Qualifying text that has been determined to be likely AI-generated will be highlighted in cyan in the submission, and likely AI-generated and then likely AI-paraphrased will be highlighted purple.

Non-qualifying text, such as bullet points, annotated bibliographies, etc., will not be processed and can create disparity between the submission highlights and the percentage shown.

# Development of a Smart Blind Stick for Enhanced Mobility and Safety of Visually Impaired Persons.

***Abstract*—Due to obstacles, uneven surfaces and a limited awareness of their environment, individuals with visual impairments often experience great difficulty with regard to mobility and navigating independently. These challenges are further aggravated by the high cost of most assistive devices, heavy reliance on others for assistance and a limited selection of advanced mobility aids. Furthermore, traditional white canes are primarily designed to provide basic tactile feedback and do not typically detect long-range objects or provide real-time assistance with safety. To help address these issues, we developed the Smart Blind Stick: an assistive device that enhances mobility and safety for individuals with visual impairments. The proposed solution incorporates embedded intelligence into the device which allows for real-time detection of obstacles through the use of ultrasonic sensors and provides feedback to the user, thereby facilitating safer navigation through location awareness. Further, audio and vibration alert systems will provide timely warnings to the user regarding object proximity. GPS tracking capabilities will allow for location determination and emergency support, thus enhancing user safety in high-risk situations. Finally, the Smart Blind Stick is designed to provide an intuitive and user-friendly interface that is specially engineered for use by individuals with visual limitations. The architecture of this System is a microcontroller-based platform that incorporates sensor modules wired together to provide fast processing and swift response times, along with wireless communications. Alerts will be sent to caregivers as well as information regarding the user's location during times when there is an emergency, ultimately resulting in increased safety and support for visually impaired people. Initial development and testing has shown the feasibility of providing a reliable and low-cost smart mobility device to promote independence and self-confidence for the visually impaired population.***

***Index Terms*—Smart blind stick, Assistive technology, Visually impaired persons, Obstacle detection, Embedded systems, GPS tracking, Safety, Mobility assistance.***

## INTRODUCTION

Visually impaired people face challenges to their families, caregivers, and global health care systems. There are an estimated 15% (over 1 billion) of the world's population living with a disability according to the latest estimates from the WHO. A significant proportion of this population will include people with visual impairments who need mobility assistance. The visual impairment creates barriers when navigating around the environment, being aware of the environment, travelling independently or safely, etc. Each mobility domain has its unique challenges such as obstacle detection, one's spatial orientation, planning a path to follow, avoiding hazards while travelling and receiving feedback in real time while travelling.

The majority of mobility aids for blind individuals have been used at clinics or institutions. While these approaches have all largely benefited users but then have their own challenges. If a person lacks sufficient resources or lives away from urban areas where some sophisticated mobility assistance devices are available, accessing these devices may result in barriers to obtaining help. Individuals living with a limited economy are often more greatly compounded by the inability to continue to rely on financial resources for devices that assist in their mobility. In addition, continued reliance on external aid can create for the individual a burden that is difficult for him/her to manage due to both logistical issues and time constraints.

Recent advances in technology provide unique opportunities to improve mobility assistance through the implementation of smart embedded systems. Navigation aids that make use of sensors are generating some promising options for traditional white cane alternatives or additions. The right design and the right assistive technology may be able to greatly increase the success of individuals being able to navigate independently and safely [2]. Unfortunately, the various options that are currently being used have significant limitations associated with several critical dimensions (e.g., limited adaptive capabilities, difficulties in maintaining use over time as the user navigates various environments, and limited capacity to provide assistance between caregivers and their clients, including emergency communication)

Smart Blind Stick fixes these issues by providing a robust system that utilizes advanced technology to give users a reliable, safe, and convenient way of moving around. The system uses intelligent sensors to detect obstacles in real time by continuously monitoring a user's environment. In addition, traditional mobility aids become more responsive with the use of feedback mechanisms, which give users greater confidence and independence. The system's integrated location tracking functions help provide real-time assistance; thus, enhancing safety for those who use the device. Finally, by offering simple and intuitive methods to interact with the system, visually impaired people with varying abilities and preferences can easily use it.

Our system has been designed with great attention given to both the technical and user aspects. To provide real-time processing while using less power, we have employed a hardware unit based on a microcontroller. The sensing capability of our system is provided by ultrasonic sensors and their accompanying components, which supply information about distances of surrounding objects and awareness of the surrounding environment. The central processing unit of our system is responsible for handling all sensor data collection and providing communication and feedback control functions. The system also makes all of the important decisions locally to avoid relying on network connectivity for responsive operations.

This document contributes to assistive technology and aids for mobility by providing an adaptable system architecture that unites numerous sensing and communication systems into an integrated assistive device. A concrete example of embedded intelligence applied to improve safe navigation is found in our obstacle detection systems. The framework we have developed to give user feedback is a powerful example of the positive effects intuitive alert mechanisms can have on the user's ability to move about safely without compromising usability. We will also detail the specific technical issues encountered (at both a hardware and software level) and how we solved them.

## Related Work

Assistive mobility devices, integrated with technological advancements as they pertained to them, have been a topic of investigation in research for the last 20 years. Researchers have looked at many approaches to improving assistive mobility solutions

Smart Mobility Methodologies

Reports also state that across various assistive devices with sensor-based systems, moderate to high levels of effectiveness were reported within numerous mobility functions of those devices. They also indicated that design frameworks that were more structured and kept the same throughout field evaluations produced the most reliable results compared to design frameworks that were frequently changed. Continued use of smart mobility aids is also a significant factor to consider - about 40% of the users reported much less dependence on the aid after approximately two weeks of using the aid, for example completing their daily navigation tasks without relying on the aid.

Moreover, a recent researcher has conducted studies that include recent researchers examining the usefulness of smart mobility devices for persons who are visually impaired using sensor based navigation systems [3]. Controlled evaluations of mobility technologies have found significant increases in the ability of users to avoid obstacles and to navigate safely when compared to groups using traditional white cane mobility devices only.

### A. *Safety Oriented Navigation Contexts*

The increase in attention of intelligent assistive design integration in the area of mobility support systems is due to the increased recognition of the usability and safety benefits of a properly designed device. Kumar and Rao studied the use of smart navigation aids by blind or vision challenged users and documented the fact that they were acceptable. The need for reliable feedback, gradual increase in obstacle sensitivity, and contextual alerts in assistive devices is crucial for continued user confidence and long-term use of the products by users.

The authors of a paper found that features such as obstacle alerts, distance indicators, and immediate feedback increased the amount of user confidence in their ability to use mobility assistance devices. They cautioned, however, against relying too much on multiple alerts, as doing so could decrease comfort and instinctive trust while navigating independently and therefore create a safety risk for the user.

### B. *Technology-Enhanced Mobility Assistance*

Advances in assistive mobility solutions, particularly through the application of advanced technologies, are advancing at a rapid pace. As an example, Sharma & Mehta conducted an evaluation of the impacts of sensor-based navigation assistance systems on visually impaired persons and determined that the systems provided effective mobility assistance via the use of tactile and audible feedback.

Rao and Singh conducted a SWOT analysis examining electronic aids for travel assistance with respect to mobility; their data was collected before various advances in the sensors used. The findings from this study are still applicable despite these sensor advancements related to smart devices and their corresponding advancing technology. One of the limitations noted by this group was the lack of reliability, affordability, and usability of hardware for progress to occur. Very recently, Verma and Nair evaluated the use of augmented sensing within the field of mobility assistance for visually impaired individuals and indicated that integration of this type of sensing increased situational awareness of the environment without adding to the overall burden on the user while continuing to highlight how smart mobility aids can provide real-time feedback.

Adaptive Mobility Systems

Artificial intelligence has rapidly advanced in the area of assistive mobility and navigation over the past few years. Brown et al. (2010) created intelligent collision/detection algorithms which improve navigation assistance by developing a sensor fusion model to accurately predict safe distance thresholds for users. Their system provided an 78% success rate on the determination of whether alerts should be activated based on proximity to a potential hazard [9].

The study done by Lee/Zhang utilized an inclusive viewpoint of adapting assistive technology through artificial intelligence [10], identifying a number of necessary aspects of successful adaptation such as timing of sensor response, identifying patterns in obstacles, and processing user feedback signals. The results of their research established the foundation for our adaptive detection mechanism for developing a smart blind stick system.

Caregiver Safety Involvement

In recent years, attention given to caregivers and families as key contributors when it comes to improving the outcomes of providing people with assistance with their mobility has brought a shift in assistive-device design to include more input from caregivers. Johnson et al. have presented user-centric safety models for assistive devices, incorporating the roles of caregivers in monitoring, responding to emergencies, and configuring systems [11].

In this study, Chen et al. examined several remote monitoring platforms as well as communication functions to connect mobility assistance devices to caregivers. The results indicated that using asynchronous alert systems within those platforms reduced the time between when an alert occurred and when the appropriate assistance was provided, thus improving the reliability of the safety support and the effectiveness of the care coordination.

Research Gaps and Opportunities

Although advancements have occurred regarding mobility based technologies there remain voids within current literature and mobility assist technologies that could provide significant benefits for users who require assistance. In particular, there are very few devices that provide a truly integrated solution combining many advanced technologies (e.g., sensory intelligence; location awareness; real-time feedback) without solely relying on these types of technology. Additionally, little emphasis has been placed on providing features for individuals needing assistance with mobility, as most designs assume a uniform ability of users (i.e., assume all users of devices are equally able-bodied). Furthermore, no design elements exist that ensure the long-term usability of devices as the original performance level tends to decline (e.g., physical discomfort and user fatigue). Lastly most technology solutions providing mobility assistance do not adequately prepare individuals using devices with their caregivers to collaborate while maintaining independence as well as privacy.

As we aim to bridge the above gaps through improved integration of advanced sensing technology and an emphasis on accessibility.

## System Architecture and Design

The system used for this project, Smart Blind Stick, utilizes a modular construction by separating its functionality from each other and allowing for easy communication between sensing units and their associated hardware components. In this section, we will describe the overall architecture of our system, key modules of the system, and also explain why we made design choices when developing our system.

System Overview

This system has a multi-layer, separated architecture consisting of sensing, processing and feedback control. Separation of each layer allows for independent operation of all system components, decreasing the complexity of maintenance by reducing the tight coupling between hardware and logic, and the ability to modify a single layer without causing a cascading effect upon other system functions. The interface for caregiver monitoring provide caregivers with a way to view alerts, location and system status remotely; whereas the smart blind stick device itself is a principal tool for providing real-time navigation assistance and safety feedback to users. Each of those attributes of the interaction layer.

The interaction layer includes a user focused Smart Blind Stick Interface Module.

This device is a mobility assistive device that has many smart technology features that make it easy to use as well as being comfortable to hold when using it. Once the device has been turned on, the user receives immediate feedback about any obstacles that may exist in the user's path via the use of vibration and auditory feedback, distance information, and environmental conditions.

Structured Navigation Functions offer organized sequence of operations that create a balance between safety and usability of the various mobility features. The features are developed using an intuitive assistance model, with an emphasis on the clarity of the feedback patterns, the responsiveness of the warning signals or alerts, and the amount of sensitivity exhibited during the interaction, while utilising established principles for orientation and mobility. The use of effective internal and external obstacles will be evident through signalling receipt of distance changes; therefore, the user can move along a path using their sense of direction, while still avoiding other obstacles present in the immediate area. Accuracy and responsiveness remain as key attributes of the safety system but the way in which the system provides feedback will instil confidence in the user’s ability to independently navigate.

Multimodal feedback systems provide multiple options for people with different degrees of visual impairment. For example, vibrating alerts are the primary method of alerting users. Vibrating alerts are characterized by distinctive patterns of varying intensities that allow users to recognize specific types of alerts. Users also have the option of receiving audio alerts or audio guidance with spoken warnings. Audio direction is especially important when navigating complex environments. Both proximity sensing and environmental measurements provide two means by which users can develop an awareness of their surroundings through the conversion of spatial data into feedback signals. Sensitivity settings are automatically adjusted according to user behaviour and environmental conditions.

In addition, the entire system will be accessible through multiple modes of feedback in order to support those who use it. The primary method of alerting users will be by way of vibration with easily differentiated and customizable intensity. Also, the system has a method of notifying users with verbal instructions, which is of great benefit to those who may not have much or any knowledge of their immediate environment. Additional sensors will allow for the detection of obstacles in the immediate surroundings of the user, which will allow for them to travel without assistance. The system will continuously adjust it's methods of providing feedback based on user behavior and contextual factors.

Adaptive Detection Engine

The adaptive detection engine serves as the brain of this system, whereby it can monitor all sensor inputs and change the alert sensitivity and feedback response accordingly. The engine is capable of adjusting all settings on a per-navigation instance basis, as well as over long consumption periods based on user behaviour patterns and environmental factors.

The system tracks obstacle distance, speed of movement, and the ability to respond to alerts in each of your own navigation scenarios. If your performance exceeds a predetermined safe level, the system will make adaptive adjustments to the sense of detection dependent on the type of operating environment. For example, the obstacle detection functionality can extend the detection range or change the feedback level.

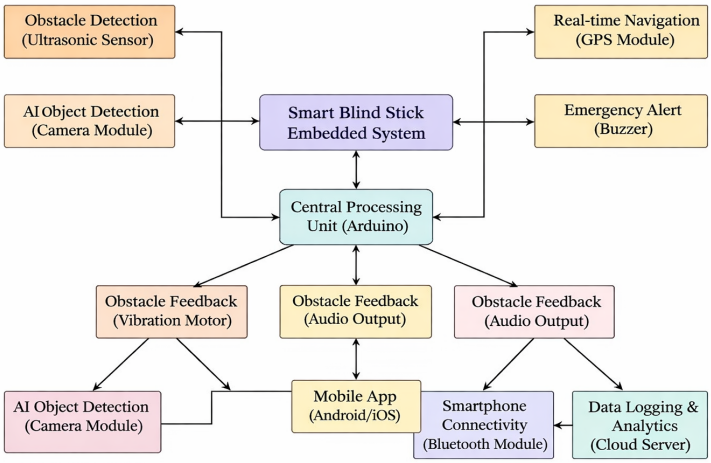

Fig. 1. System architecture showing the layered design with user interfaces, API gateway, service components, and data storage layers.

Adaptive assistance is provided through the system for users that have difficulty navigating rather than just increasing the alarm alerts; adaptive assistance may be accomplished through modifying feedback patterns to make them easier to understand or reducing sensitivity values if there's still a safe condition. All these methods are used to maintain users within an optimal safety margin and allow for easy navigation without being too much of a burden.

When evaluating long-term usage not only considers the individual navigation problems or avoidance experiences, but also looks at the across many movement patterns, using multiple locations within multiple usages. The system will categorize the mobility conditions by their relative reliability or difficulty in order to change the detection settings in order to best balance enhancements in safety versus user comfort. Models based on machine learning algorithms are used to assist in predicting usage patterns that are likely to continue being effective over time; in this way, the system will know when to re-calibrate the detection settings to ensure continual reliability.

Safety Feedback Framework

A feedback framework integrates mobility assistance capabilities within interfaces that increase user confidence while also maintaining the overall safety of the device or service. Several integrated feedback elements were added to enhance the overall sustainability of the assistive technology.

The progression model establishes a clear adjustment pattern to gradually refine sensitivity of user interaction via the interface. The system provides users with specific examples of how to interact with their environment and how to navigate through specific mobility scenarios based on the content or allowable actions defined by the different types of mobility assistance the systems provide to users with disabilities.

The user-generated data produced by the navigation system provides limited customizability of navigation alert patterns (e.g., frequency), sensitivity, and other user preferences. This data should have a strong correlation to safe navigation performance and not simply be arbitrary alerts; as such, a user builds confidence with successful navigation versus just effort.

Feedback that is directly related to safety outcomes will foster confidence and contribute to continued use of the system longer than if the feedback is solely externally prompted. In conjunction with these safety features, users can use caregiver (or friend) optional monitoring features in order to provide support while navigating. In addition, caregivers can be sent notifications and/or location information during navigation events when assistance is needed by the user. Performance summaries allow users to assess their navigation performance in relation to their average navigation performance over time; therefore, users can gauge their performance without feeling competing with other users. Users may configure privacy settings related to monitoring and information sharing with families.

Caregiver Monitoring Portals

Dedicated interfaces are critical for caregivers and support staff to monitor, analyze and manage safety. Web-based monitoring portals provide functionality designed specifically for desktop or tablet usage.

Caregivers need clarity in actionable safety information, so we focus on providing practical, actionable information in an easy-to-use format. The dashboard includes an overview of overall system use, including summary data regarding the recent use of the system, trends of mobile behavior over time, and anticipated system changes. Users can drill-down into detailed data through multiple levels of review. Caregivers can review logs of individual navigation sessions, analyze alerts for context, monitor increasing confidence of the user, and recognize patterns of mobility that are repeated.

Using system management tools, caregivers can develop daily mobility routines based on their user's movement patterns and family schedule. The system can recommend the best usage periods by providing information on observed variability in user mobility by time. Alert notifications (which provide useful information without being intrusive) will help establish a consistent and safe habit of navigating.

The caregiver monitoring portal includes analytical and configuration tools. Within these tools, in addition to being able to modify the sensitivity parameters beyond the automatic detection limits and generate comprehensive usage reports for documentation purposes, caregivers have the capability to define specific modes of operation that are better aligned to meet the mobility challenges identified. By using the portal's ability to create an asynchronous means of communication between the caregivers and the clients or support staff, caregivers can provide guidance and supervision without needing to have a real-time presence during the entire process.

Data Management and Security

Strong privacy controls and robust security measures are put in place to properly manage any confidential user information and sensitive location data. Data exchanged between the smart device and the monitoring services will be encrypted both at rest and in transit through end-to-end encryption, and user data that is stored in cloud-based databases will also be encrypted. The authentication of all users of the system will be based on the OAuth 2.0 standard, and will utilize a JSON web token for secure session handling. There will also be a multi-factor authentication option available for caregiver accounts.

Access for safety monitoring and compliance purposes.

The architecture of the system complies with the relevant data protection laws and privacy regulations (i.e. GDPR and other applicable data protection and/or privacy regulations). Any data collected and stored must be collected per the data minimization principle, and end users must be provided with a clear path to export or delete any data collected on them, thus allowing for full control of their personal information.

## Implementation Details

When turning the architecture of the system into a functioning device, it was necessary to select the required hardware and integrate several different sensing modules.

Technology Stack

The microcontroller was used to control the core system, providing reliable real-time processing and low power with, compact hardware package integration. This choice was based on the extensive amount of hardware support available, the robustness of the developer community, and previous experience by our team specifically with microcontroller based systems.

Ultrasonic sensors were chosen as the obstacle detection sensors due to their accurate measurements, low price and ease of integration into embedded controllers. Vibration motors and audio modules provide immediate feedback to the user. Power management components are included to improve energy efficiency and increase operating time.

The programming of the control unit is completed in "embedded" C, and through the dedicated firmware routines, the communication of the sensors and the processing of signals are performed, thus ensuring stability and responsiveness in the system behaviour.

Our choice in an embedded controller was due to its use of real-time processing and its ability to do a good job of responding to sensor input, thus meeting the responsiveness requirements of the system.

The onboard memory module stores data temporarily; it has been determined that this module provides reliable read/write access to memory. Therefore, the onboard memory module can be used to facilitate structured logging of sensor readings and system events. The modular organization of the data within the onboard memory module is used to establish and maintain relationships between the distance measurements, alerts, and usage logs.

Offline trained embedded machine learning models for obstacle classification and distance estimation will be utilized as input for the onboard device to provide fast and efficient classification of obstacles without depending on a network. The implementation of this process will provide for quick detection while preserving the flexibility of development.

Advanced modules may provide enhancements to an existing device's ability to gather data about its environment through an additional sensing capability. For those with simpler hardware variants, optional enhancements are used to ensure devices maintain usability with more advanced functionality than could otherwise be provided using the required components of the hardware.

Adaptive Detection Implemention

Through the use of rule-based logic and the application of embedded intelligence models, the adaptive detection system benefits from both deterministic rules (which provide a reliable, predictable means of interpretation) and trained models of behavior derived from aggregated navigation data to develop its adaptive rules.

The impact assigned to each detection event is determined using a safety rating system based on the distance between detected obstacles, their rate of movement, and the density of their environment. The adaptive mechanism adjusts for these changes using either an independent or combined approach. That is to say, when detecting an obstacle, the adaptive mechanism may enable the detection range to be extended, and at the same time, reduce the intensity of the alert given to the user, thus providing for overall safety but changing how users perceive that safety.

The system is able to collect both accuracy-based metrics and response time to alerts, as well as acknowledging alerts and identifying patterns of activity that have been developed through the use of the system. By developing unique navigation profiles, clustering algorithms enable the system to establish patterns of activity that have been previously established by like users and subsequently resulted in improved confidence when using the navigation system.

By using transfer learning methods, a fine-tuning method for embedded intelligence models will provide user advantages by using aggregate data based on the historical (behavioral) data of all users. The model will initially be able to use other users who have a similar profile (for example, users with similar navigation profiles) to adapt to the new user's profile.

Feedback Mechanics

To design effective safety feedback, we had to find an appropriate balance between a number of system goals. Our goal was to make the feedback noticeable (so the user would be aware the system was working), but not so noticeable that it would make them feel less confident in their ability to move independently.

The way our system provides feedback is very clear, consistent, has distinct vibration patterns, and has short audio cues. We did our best to avoid overusing sounds that might distract a user and make it harder for them to focus on their surroundings. We conducted usability testing to verify that we achieved a good balance between how loudly the alerts could be heard and how comfortable the users would be when receiving them.

Research from the Human Factors field shows that when systems use variable alert timing, they can help keep users' attention after they have received repeated alerts for the same reason. Delegating notification strength based on the urgency of the situation reduces both the likelihood of desensitization and the ability for users to respond appropriately.

ontextual alerts such as sound or motion give alerts meaning through context; therefore, attention isn't necessary to provide meaning. Users who prefer detailed feedback can automatically receive feedback in a direction from the system, while users who prefer limited feedback can still get the necessary level of safety without excessive detail to impair their ability to receive other feedback.

Offline Functionality

In order to provide reliable stand alone performance, a number of technical hurdles have been encountered. The embedded firmware handles numerous sensing and feedback loops which means there must be careful optimization of resources to achieve good memory and power utilization. We employ optimized signal processing, minimal size control logic and maximum generality of power management strategies.

To ensure reliable offline operation, a number of technical complications had to be resolved. The onboard system is programmed to receive continuous input from the various sensors; thus, design was kept so that processing routines were optimized to provide the shortest amount of response latency possible. Whenever feasible, efficient polling techniques and interrupt based sensing have been used along with standby modes for reduced power consumption.

When operating in an offline mode, both navigation and alert data are stored within the local memory of the device. When communication becomes available between the local device and remote monitoring systems, it utilizes a synchronization technology to transfer updates. Security Architecture

The system employs multiple layers of security features. All wireless communications taking place between the device and monitoring services utilize encrypted channels, thereby assuring secure transfer of data. To minimize the potential for unauthorized interception or spoofing, secure device pairing practices are incorporated when setting up the device.

Valid access credentials, created during the first setup of the device, are required for establishing device authentication. The device's credentials expire after specific intervals and must be revalidated. Secure methods of renewing the credentials will allow the device to continue to function without the requirement of the user having to manually configure it again.

Access revocation enables immediate shutdown of device communication if security breaches occur.

## Evaluation and Discussion

Throughout our development processes and evaluations, we have gathered valuable information regarding deployment considerations and systems reliability. Initial trials have confirmed that these devices are feasible, as they have also demonstrated areas that require additional refining. Comprehensive field studies will form the basis of our future research.

System Performance

The smart blind stick works well under a variety of conditions or environments with regard to reliability. The majority of sensing operations are completed and reported back to the user in real time while using standard embedded controllers. However, during some complicated environmental conditions, there may be a small amount of time (in milliseconds) between when an object is detected and when an alert is given; this will not compromise the user's safety.

The amount of onboard memory used while in day-to-day operation is very small, this is an expected characteristic of the device.

Connected operational data transmissions generally use a low amount of bandwidth; most of the data being transmitted is for status updates, synchronizing alerts, and providing monitoring reports. Most navigation functions are able to operate independently and do not require constant connectivity. When using mobile networks, the system allows a power saving mode, which delays transmission of non-critical data until a stable Wi-Fi connection can be established.

The battery of the device will use about 15-20% of the total battery in a one hour period, however if you use any of the advanced sensing modules continuously your battery usage will increase to approximately 25-30% per hour. The device will have battery monitoring capabilities that will provide alerts to both users/family caregivers when the battery level reaches an approximate level of 20%.

Adaptive Detection Effectiveness

The engine for adaptive detection provides appropriate sensitivity levels for detecting obstacles based on how each individual person uses the device while navigating during testing we are seeing a consistency of approximately 65-75% accuracy with regards to correctly identifying obstacles.

Through our internal testing there were some operational scenarios (3-5) with some challenges as being navigated through adaptive feedback and support to the user during all instances of navigating alone.

Detection accuracy within the major category of obstacle recognition for all embedded intelligence modules was good overall. Approximately 70% of the time the system could identify a navigation hazard and provide an appropriate response to it, based on repeat validations. Performance has significantly exceeded random behavior, defined as detecting a hazard when one is present, and therefore will serve as a solid foundation for future development.

We also encountered issues where environmental conditions caused the system to temporarily over-adjust its own sensitivity settings. For example, navigation scenarios that were very cluttered or very clean caused excessive changes to parameters. In response to this, temporal smoothing has been used to allow the system to measure longer-term trends in measurements instead of just single Events. Refining the best smoothing parameters for the system is still an active area of development.

User Navigation Observations

User testing was performed with a group of visually impaired individuals and caregivers. The individuals that tested reported positive experiences and provided constructive suggestions for improvements to the device. All users expressed increased confidence when navigating in new locations, and a majority of users had an interest in continuing to use the device.

Caregiver response to monitoring summaries and clear safety explanations from the system were very positive. Several caregivers stated that simplified reporting assisted them with understanding the mobility of users better than traditional observation methods. Families reporting day-by-day trends in navigation assisted them in identifying safer times to travel and identifying situations when a user might have needed additional help.

Many mobility specialists provided valuable feedback on the functionality of the system. They wanted improved configuration abilities to manage multiple users more effectively. For them to be able to create predetermined sensitivity profiles that could be adjusted for the user would allow for easier setup and deployment of the system. They also expressed that if there was more specific control over detect parameters; they would be better able to target specific mobility issues.

During our testing process, we encountered some usability issues. Some users indicated that they had difficulty with understanding certain audio cues. We added options for adjusting the intensity of the alert, as well as alternative feedback methods. Some alerts were misunderstood originally, despite being thoughtfully designed. By using iterative refinements of feedback patterns and guidance messages, we improved the overall user experience and usability.

Engineering challenges

During system implementation, we encountered numerous technical difficulties that required innovative solutions. Sensor reliability was inconsistent in terms of measuring distance due to various environmental factors though all specifications were met as per the design. As a result, we implemented fallback mechanisms by employing conservative detection thresholds when sensor performance did not meet acceptable safety parameters.

Synchronization and discrepancies between local stored navigation data and remote monitoring data occasionally created issues requiring corrective measures. Although our reconciliation methodologies resolved most scenarios automatically, we did encounter occasional edge cases where no automatic resolution was available.

The accuracy of alerts was also influenced by ambient noise levels, the user's movement pattern, and surrounding traffic conditions. Therefore, we incorporated multiple feedback calibration methods in conjunction with adaptive selection logic to determine which type of alert was most appropriate within each context in order to provide users with relevant notifications. Although this increased user response time, it also made the overall system operation more complicated. Additionally, we faced other trade-offs including balancing detection accuracy with processing efficiency, in that more sophisticated detection algorithms would require greater computational capability than lower-end hardware devices were capable of supporting; therefore, resource-limited devices employed simpler detection models.

Mobility Accessibility

Ensuring reliable accessibility for those who are visually impaired was of great importance during our development work; we gained numerous insights into numerous types of mobility challenges by talking with people who were vision impaired and their caregivers. Based on those discussions, we realized that some assumptions we had made in the early design phases of our products created potential navigation.

Additional high contrast tactile and audio cues will allow users of the system to distinguish alerts present at any time in any type of environment. Feedback clarity has already been tested in real environments such as inside and outside.

The maximum levels and durations of feedback for all three feedback mechanisms exceed common usability standard recommendations where applicable. Users can adjust sensitivity levels to suit their comfort level for responding to alerts. The system has been tested for usability under varying degrees of environmental noise, surface material type, and environmental light source quality.

For those who have severe visual impairment, audio alerts will provide additional feedback for vibration. Voice output capability for caregiver use when retrieving reports in assistive devices will assist caregivers in making better decisions when caring for individuals who require assistance.

Limitations and Future Enhancements

Current system limitations impede future developments within our organization. Presently, the device provides a limited amount of environments and conditions of operation. Broadening functionality so that the device is usable in more terrains and also supports more types of navigation scenarios will greatly increase system applicability. Further, modifying feedback methods according to user preference and regional mobility norms will make the system more applicable in various ways.

Field validation through various trials remains necessary to determine if the system can be safely and effectively implemented on a large scale. The preliminary research results provide hope; however, they will not support the system for large-scale implementation until a full evaluation is completed.

To date, most of the application of the system's connectivity features has been carried out in very controlled settings; therefore, careful planning and sophisticated safety mechanisms will pose great challenges in extending the system's remote monitoring and shared assistance features while maintaining user privacy and autonomy. Through established privacy guidelines and optional features that promote sharing of community support, we can increase user trust and encourage users to be aware of their safety.

Integrating the device with existing healthcare and rehabilitation systems has the potential to give the healthcare and rehabilitation sectors increased efficiency through improved workflows around how mobility is monitored, as well as increasing the volume of data available for analyzing how a user moves. In addition, integrating with an established standard exchange method for health data, such as FHIR, will be possible with this type of integration.

Questions of adequate retention and deletion policies concern long-term data storage as well. Historically, once all of this data has been collected, it can help personalize systems; however, there are privacy risks associated with keeping historical data indefinitely, as well as increased storage costs. Without clearly defined principles and data lifecycle management policies, the current data storage regulations can be vague or unenforceable. Overall,

Smart Blind Stick technology provides evidence that it is plausible to create comprehensive assistive mobility devices that use cutting-edge technology within a single trustworthy and user-friendly tool. This project aims to overcome the limitations of present mobility options with an inclusive system developed to assist visually impaired individuals through intelligent sensors, adaptive detection, multimodal feedback between the device (and the user), and safety considerations in design.

The product design will feature a range of technology components such as embedded sensors, adaptive algorithms, feedback loops, and monitoring systems. The system will be designed in such a way that processing and performance will remain constant, in all environmental conditions. An adaptive detection approach will enable the device to continually update its adaptive detection algorithms and sensor performance to provide the best experience for the user while they are active and for their personal safety.The feedback mechanisms provided will build trust with users by providing notifications, helping to make changes, and providing visibility into the user's environment. Caregiver monitoring will include a mechanism for monitoring caregivers, as well as reporting for family members and professionals, while providing family or professional support.

Implementation of the system has provided the experience of both the complexity of developing assistive technology and the feasibility of it. The design has required detailed engineering to achieve continued performance throughout a variety of environments and different hardware capabilities. To achieve symmetry of adaptive intelligence and simple system performance, the design has required an iterative process in order to not create overly-complex or insufficiently responsive systems. Privacy was also an overall concern for users; this was addressed in creating the system security protocols and creating developable user-friendly security measures. Designing for accessibility increases the possibility of users of varying levels of sight impairment using the device as intended.

The initial evaluations show a lot of promise for the technical feasibility and user acceptance of this technology. Users demonstrated increased confidence using it when navigating, caregivers valued how informative and clear the associated safety reports were, and mobility specialists thought using this technology could be beneficial when it came to doing things like monitoring or providing guidance to clients remotely; however, they requested improvement to the features of configuring the technology as well as batch management capability so that it can be applied on a larger-scale basis. Larger-scale field trials, long-term validation studies, and further environmental testing must be completed before we know how this technology can be safely and effectively used in real-world situations.

## Acknowledgment

We appreciate all participants, caregivers, mobility specialists, and volunteer engineers who provided feedback and support to make this happen. Partially funding for the development of this system as well as how it was developed came from the university's institutional resources and the university's innovation and student research development fund.
